#### 4.6: Ambiguity of Grammars

In this section, we say what it means for a grammar to be ambiguous. We also give a straightforward method for disambiguating grammars for languages with operators of various precedences and associativities, and consider an efficient parsing algorithm for such disambiguated grammars.

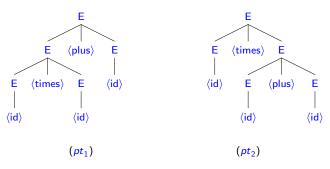

#### Motivating Example

Suppose *G* is our grammar of arithmetic expressions:

$$\mathsf{E} \to \mathsf{E} \langle \mathsf{plus} \rangle \mathsf{E} \mid \mathsf{E} \langle \mathsf{times} \rangle \mathsf{E} \mid \langle \mathsf{openPar} \rangle \mathsf{E} \langle \mathsf{closPar} \rangle \mid \langle \mathsf{id} \rangle.$$

Question: are there multiple ways of parsing the string  $\langle id\rangle\langle times\rangle\langle id\rangle\langle plus\rangle\langle id\rangle$  according to this grammar?

Answer: Yes:

# Definition

In  $pt_1$ , multiplication has higher precedence than addition; in  $pt_2$ , the situation is reversed. Because there are multiple ways of parsing this string, we say that our grammar is "ambiguous".

A grammar G is ambiguous iff there is a  $w \in (alphabet G)^*$  such that w is the yield of multiple valid parse trees for G whose root labels are  $S_G$ ; otherwise, G is unambiguous.

# Examples

The grammar

$$A \rightarrow \% \mid 0A1A \mid 1A0A$$

is a grammar generating all elements of  $\{0,1\}^*$  with a **diff** of 0, for the diff function such that diff 0 = -1 and diff 1 = 1.

It is ambiguous as, e.g., 0101 can be parsed as 0%1(01) or 0(10)1%.

In Section 4.5, we saw another grammar for this language:

$$A \rightarrow \% \mid 0BA \mid 1CA,$$
  
 $B \rightarrow 1 \mid 0BB,$   
 $C \rightarrow 0 \mid 1CC,$ 

which turns out to be unambiguous.

# Disambiguating Grammars of Operators

Not every ambiguous grammar can be turned into an equivalent unambiguous one. However, we can use a simple technique to disambiguate our grammar of arithmetic expressions, and this technique works for many commonly occurring grammars involving operators of various precedences and associativities.

Since there are two binary operators in our language of arithmetic expressions, we have to decide:

- whether multiplication has higher or lower precedence than addition; and
- whether multiplication and addition are left or right associative.

As usual, we'll make multiplication have higher precedence than addition, and let addition and multiplication be left associative.

As a first step towards disambiguating our grammar, we can form a new grammar with the three variables: E (expressions), T (terms) and F (factors), start variable E and productions:

```
\begin{split} \mathsf{E} &\to \mathsf{T} \mid \mathsf{E} \langle \mathsf{plus} \rangle \mathsf{E}, \\ \mathsf{T} &\to \mathsf{F} \mid \mathsf{T} \langle \mathsf{times} \rangle \mathsf{T}, \\ \mathsf{F} &\to \langle \mathsf{id} \rangle \mid \langle \mathsf{openPar} \rangle \mathsf{E} \langle \mathsf{closPar} \rangle. \end{split}
```

The idea is that the lowest precedence operator "lives" at the highest level of the grammar, that the highest precedence operator lives at the middle level of the grammar, and that the basic expressions, including the parenthesized expressions, live at the lowest level of the grammar.

Now, there is only one way to parse the string  $\langle id\rangle\langle times\rangle\langle id\rangle\langle plus\rangle\langle id\rangle$ , since, if we begin by using the production  $E\to T$ , our yield will only include a  $\langle plus\rangle$  if this symbol occurs within parentheses.

If we had more levels of precedence in our language, we would simply add more levels to our grammar.

On the other hand, there are still two ways of parsing the string  $\langle id \rangle \langle plus \rangle \langle id \rangle \langle plus \rangle \langle id \rangle$ : with left associativity or right associativity.

To finish disambiguating our grammar, we must break the symmetry of the right-sides of the productions

$$E \rightarrow E\langle plus \rangle E,$$
  
 $T \rightarrow T\langle times \rangle T,$ 

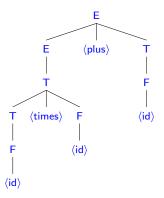

turning one of the E's into T, and one of the T's into F. To make our operators be left associative, we must use *left recursion*, changing the second E to T, and the second T to F; right associativity would result from making the opposite choices, i.e., using *right recursion*.

Thus, our unambiguous grammar of arithmetic expressions is

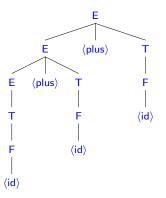

```
\begin{split} \mathsf{E} &\to \mathsf{T} \mid \mathsf{E} \langle \mathsf{plus} \rangle \mathsf{T}, \\ \mathsf{T} &\to \mathsf{F} \mid \mathsf{T} \langle \mathsf{times} \rangle \mathsf{F}, \\ \mathsf{F} &\to \langle \mathsf{id} \rangle \mid \langle \mathsf{openPar} \rangle \mathsf{E} \langle \mathsf{closPar} \rangle. \end{split}
```

It can be proved that this grammar is indeed unambiguous, and that it is equivalent to the original grammar.

Now, the only parse of  $\langle id \rangle \langle times \rangle \langle id \rangle \langle plus \rangle \langle id \rangle$  is

And, the only parse of  $\langle id \rangle \langle plus \rangle \langle id \rangle \langle plus \rangle \langle id \rangle$  is

# Top-down Parsing for Grammars of Operators

Top-down parsing is a simple and efficient parsing method for unambiguous grammars of operators like

```
\begin{split} \mathsf{E} &\to \mathsf{T} \mid \mathsf{E} \langle \mathsf{plus} \rangle \mathsf{T}, \\ \mathsf{T} &\to \mathsf{F} \mid \mathsf{T} \langle \mathsf{times} \rangle \mathsf{F}, \\ \mathsf{F} &\to \langle \mathsf{id} \rangle \mid \langle \mathsf{openPar} \rangle \mathsf{E} \langle \mathsf{closPar} \rangle. \end{split}
```

Let  $\mathcal{E}$ ,  $\mathcal{T}$  and  $\mathcal{F}$  be all of the parse trees that are valid for our grammar, have yields containing no variables, and whose root labels are E, T and F, respectively.

Because this grammar has three mutually recursive variables, we will need three mutually recursive parsing functions,

$$\begin{split} & \mathsf{parE} \in \mathsf{Str} \to \mathsf{Option}(\mathcal{E} \times \mathsf{Str}), \\ & \mathsf{parT} \in \mathsf{Str} \to \mathsf{Option}(\mathcal{T} \times \mathsf{Str}), \\ & \mathsf{parF} \in \mathsf{Str} \to \mathsf{Option}(\mathcal{F} \times \mathsf{Str}), \end{split}$$

which attempt to parse an element pt of  $\mathcal{E}$ ,  $\mathcal{T}$  or  $\mathcal{F}$  out of a string w, returning **none** to indicate failure, and some(pt, y), where y is the remainder of w, otherwise.

Given a string w, parE operates as follows. Because all elements of  $\mathcal{E}$  have yields beginning with the yield of an element of  $\mathcal{T}$ , it starts by evaluating parT w. If this results in none, it returns **none**. Otherwise, it results in some(pt, x), for some  $pt \in \mathcal{T}$  and  $x \in Str$ , in which case parE returns parELoop(E(pt), x), where  $parelloop \in \mathcal{E} \times Str \rightarrow Option(\mathcal{E} \times Str)$  is defined recursively, as follows.

Given  $(pt, x) \in \mathcal{E} \times Str$ , parELoop proceeds as follows.

- If  $x = \langle plus \rangle y$  for some y, then **parELoop** evaluates **parT** y.
  - If this results in **none**, then **parELoop** returns **none**.
  - Otherwise, it results in some(pt', z) for some  $pt' \in \mathcal{T}$  and  $z \in Str$ , and parELoop returns  $pareLoop(E(pt, \langle plus \rangle, pt'), z).$
- Otherwise, parELoop returns some(pt, x).

The function parT operates analogously.

Given a string w, parF proceeds as follows.

- If  $w = \langle id \rangle x$  for some x, then it returns  $some(F(\langle id \rangle), x)$ .
- Otherwise, if  $w = \langle \text{openPar} \rangle x$ , then **parF** evaluates **parE** x.
  - If this results in none, it returns none.
  - Otherwise, this results in some(pt, y) for some  $pt \in \mathcal{E}$  and  $y \in Str$ .
    - If  $y = \langle \mathsf{closPar} \rangle z$  for some z, then  $\mathsf{parF}$  returns  $\mathsf{some}(F(\langle \mathsf{openPar} \rangle, pt, \langle \mathsf{closPar} \rangle), z)$ .
    - Otherwise, parF returns none.
- Otherwise parF returns none.

Given a string w to parse, the algorithm evaluates parE w. If the result of this evaluation is:

- none, then the algorithm reports failure;
- some(pt, %), then the algorithm returns pt;
- some(pt, y), where  $y \neq \%$ , then the algorithm reports failure, because not all of the input could be parsed.
